24 Abstract

25 Aim: Determining whether altitudinal shifts in species distributions leave molecular

26 footprints on wild populations along their range margins from rear to leading edge.

27 Location: South-west France.

Methods: We compared the demographic and genetic variation in 42 wild populations of the
Western oviparous subclade B2 of a cold adapted lizard (*Zootoca vivipara louislantzi*). These
populations can be divided into four ecological units across altitudinal clines in South-west
France (rear edge: <100 m, admixture zone: 100-500 m, continuous range: 500-1300 m and
leading edge: >1300 m above sea level).

Results: Within the rear edge were found the highest levels of inbreeding, genetic 33 differentiation and evidence of interrupted gene flow compared to central or colonising areas. 34 35 Within the leading edge, altitudinal range expansion occurred over the last centuries and populations showed relatively low genetic diversity. These demographic and genetic trends 36 37 were better explained by inhospitable (warm and dry) climate conditions and forest cover. Main conclusions: This empirical evidence illustrates that molecular footprints of climate 38 conditions and habitat quality on wild population trends can be perceived after recent events, 39 which should be of particular importance to accurately understand and anticipate human-40 induced global change on wild species and ecosystems. 41

population decline, structuration

45 Introduction

Biodiversity is facing a global loss of habitats resulting in altered species and biotic 46 47 interactions worldwide (Ceballos et al., 2017; Plotnick et al., 2016; Wiens, 2016). Causes are 48 multiple, often synergetic, and have various footprints from genes to ecosystems (Pecl et al., 49 2017). As a consequence, many species' distributions are shifting (Lenoir et al., 2020; VanDerWal et al., 2013) and these range shifts have direct impacts on processes and patterns 50 51 of population genetics (Carvalho et al., 2019; Hampe & Petit, 2005; Templeton et al., 2001). In particular, once populations at the rear edge become isolated, the loss of connectivity and 52 immigration progressively leads to an increase in inbreeding through genetic drift, one of the 53 54 main precursor of decline in small populations (Frankham, 2010; Hampe & Petit, 2005). In contrast, at the leading edge, newly favourable habitats should be colonized by few 55 individuals resulting in founder events, which implies lower genetic diversity associated with 56 small groups of emigrants and recurrent extinction events (Hampe et al., 2013; Hampe & 57 Petit, 2005; Nadeau & Urban, 2019; Vilà-Cabrera et al., 2019; Waters et al., 2013). Studies 58 59 have challenged these general assumptions since genetic diversity does not necessarily correlate with biogeography (Eckert et al., 2008; Pironon et al., 2017) nor does it explain 60 population decline (Tobler et al., 2013). This prompts for empirically testing patterns of 61 62 genetic variation and phylogenetic history along colonization gradients to better understand how population genetic diversity or structure correlate with range shifts of wild populations. 63

Terrestrial ectotherms are well suited organisms for this purpose since their ecology
and demography tightly depend on climate conditions and landscape structure (Le Galliard et
al., 2012). These organisms are characterized by a strong thermal dependence on their
performance, which may explain their spatial distribution (Buckley et al., 2012). Under
temperate climates, ectotherm distributions at a continental scale have been strongly
influenced by past Quaternary climatic oscillations resulting in successive range expansions

and range contractions in glacial refugia (Hewitt, 2000). These historical changes must be 70 71 considered to address current patterns of genetic variation at a regional scale, especially to characterise the recent impacts of climate change. Indeed, terrestrial ectotherms in their 72 73 trailing range edge (low latitudes and low altitudes) are now increasingly challenged by 74 recurrent temperatures nearing their upper thermal safety margin (Sunday et al., 2014). Despite a relatively high potential of phenotypic plasticity, once temperatures rise above 75 76 maximal critical temperatures, individuals at the rear edge of the distribution are exposed to greater risks of overheating and dehydration, which can impair the activity time and incur 77 physiological costs (Dupoué et al., 2018, 2020; Le Galliard et al., 2012; Rozen-Rechels et al., 78 79 2019; Sinervo et al., 2010). These extreme climate conditions may constrain lifetime 80 reproductive success and/or longevity, eventually leading to a loss of reproductive individuals and population extirpation (Bestion et al., 2015; Dupoué, Rutschmann, Le Galliard, Clobert, 81 82 et al., 2017; Lourdais et al., 2017).

The present comparative study assessed relative abundance and genetic profiles in 83 natural populations of the Western oviparous subclade B2 of the common lizard (Zootoca 84 vivipara louislantzi) along an altitudinal cline. This boreal Squamate is a cold adapted 85 specialist combining freezing tolerance to supercooling physiological adaptations (Voituron et 86 al., 2002), as well as reproductive bimodality with distinct oviparous and viviparous 87 88 populations across its distribution range (Surget-Groba et al., 2006). The viviparous form has 89 colonized the Eurosiberian region from Western Europe to Hokkaido island in Japan being 90 restricted by the polar circle (Surget-Groba et al., 2006). In the Southwest margin of its range, the oviparous form (Z. v. louislantzi) experiences a spatially restricted distribution that has 91 92 been structured across altitude most likely due to temperatures and anthropogenic habitat fragmentation. Populations were affiliated to four ecological units defined a priori and 93 following the classification established by Hampe & Petit (2005). This allows for the 94

examination of recolonization dynamics and how multiple demographic trajectories shape 95 96 genetic variation since the Last-Glacial-Maximum (LGM). In the rear edge within 100 m above sea level (ASL), man-made draining of natural habitats (peatbogs and marshes) 97 occurred in the mid-19th century, which has isolated populations into a few suitable patches of 98 humid areas [boggy islets (Berroneau, 2014)]). Surrounding environments became 99 inhospitable because of human landscape modification and recent climate warming, thus 100 101 hindering any emigration from these populations. Similar anthropogenic-driven isolations have occurred in the foothills of the French Pyrenees Mountains between 100 and 500 m 102 ASL, where populations are enclaved within forest-isolated peat bogs. This area is located 103 104 between populations from the rear edges and those of the continuous range, now forming the 105 Admixture zone [sensu (Hampe & Petit, 2005)], a lineage mixing area between previously allopatric sub-clades (Rius & Darling, 2014). On the other hand, in its continuous range from 106 107 500 to 1,300 m ASL, populations occupy various habitat types mostly composed by river ecosystems and forest borders. Finally, populations are now expanding above 1,300 m ASL 108 and colonizing highland meadows, which represent the leading edge. 109

We used microsatellite polymorphisms to assess how 42 natural populations across 110 this cline differed in genetic structure, diversity and connectivity. We anticipated that 111 Pyrenean ascension occurred a few times after the LGM, similar to the latitudinal expansion 112 of the viviparous form of this species (Horreo et al., 2018). Additionally, we examined how 113 human-induced environmental threats may additively affect lizard populations by testing the 114 115 specific influence of recent climate conditions and habitat characteristics on demographic and genetic markers. Because rear edge populations are exposed to increasingly hostile (warm and 116 117 dry) thermal conditions, they should also experience high levels of differentiation and inbreeding reflecting range contraction (Hampe & Petit, 2005). Conversely, in the wave front 118 of the expanding margin, we predicted higher segregation and lower genetic diversity if 119

colonisation occurs through founder events (Hampe et al., 2013; Nadeau & Urban, 2019; 120 121 Waters et al., 2013). Finally, we expected demographic and genetic variation to be negatively impacted by constraining climate conditions and low habitat quality. We tested this prediction 122 123 by checking the influence of two climate variables (i.e., air temperature and precipitation flux) and two habitats characteristics (i.e., forest cover and wetland potential) that are known to 124 drive ecophysiological adjustments and local adaptations in this species (Dupoué, 125 126 Rutschmann, Le Galliard, Clobert, et al., 2017; Dupoué, Rutschmann, Le Galliard, Miles, et 127 al., 2017; Lorenzon et al., 1999; Rozen-Rechels et al., in press; Rutschmann et al., 2016,

128 2020).

129

130 Material and methods

131 Sampled populations among four ecological units

We caught 627 individuals from 42 populations between April-August 2017 and in May 132 133 2018. Populations were selected and considered different based on natural barriers (rivers, forests, altitude) and a minimal 2 km plane geographic distance (~300 m of altitude 134 differential). Following capture, lizards were swabbed in the buccal cavity (Beebee, 2008), 135 136 and samples were immediately stored in TE buffer and frozen at -20°C the same day to optimize DNA conservation until extraction. In each population, we estimated the relative 137 138 abundance as the number of lizards captured divided by the time spent on the population and the number of people (range: 2-4 persons). As a heliothermic thermoregulator, common 139 lizards rely on solar radiation to regulate body temperature, and capture probability may 140 depend on weather conditions. We limited this bias by sampling all populations under 141 relatively similar weather conditions (< 50% cloud cover) during the activity peak time (10:30 142 - 17:30) as long as basking opportunities remained available. In addition, cloud cover (0-50 143

%) had no statistical influence on abundance estimate (p = 0.626) and a similar index 144 145 provided a reliable proxy of absolute density in another study (Dupoué, Rutschmann, Le Galliard, Clobert et al., 2017). Populations were divided into the four ecological units based 146 147 on their altitude thresholds as described above (100, 500, and 1,300 m) and the associated landscapes (Table S1). This included the boggy islets in the rear edge (n = 55 lizards among 4 148 populations), the forest enclaves of the admixture zone (137 lizards among 9 populations), the 149 150 mixed habitats of the continuous range (242 lizards among 16 populations), and the highland meadows in the leading edge (198 lizards among 13 populations). 151

152 *Climatic conditions and habitat characteristics in sampled populations*

For each population, we extracted two climate variables (temperature and precipitations) of 153 recent climate conditions from CHELSA database, where climatology is averaged between 154 1981 and 2005 (Karger et al., 2017, 2020) and is available at a high resolution of 30 Arcsec 155 (~1 km²). For each population, we considered the annual near-surface (2 m) air temperature 156 157 (Fig. S1A) and annual cumulative precipitation flux corrected by orographic effects (Fig. 158 S1B). We also considered two descriptors of habitat quality relevant for this species: forest cover and wetland potential. We estimated forest cover at a precision of 30 m from the 159 aboveground live woody biomass density for the year 2000 (Fig. S1C), derived from many 160 161 studies (http://www.globalforestwatch.org/). Wetland potential (the probability for the habitat to be a humid zone ranging from 0 to 3; 0: dry environments; 1: good probability of wetland 162 area; 2: strong probability of wetland area; 3: very strong probability of wetland area) was 163 obtained at a precision of 50 m (Fig. S1D), calculated from pedological and hydrogeological 164 information (Berthier et al., 2014). This index provides a continuous measure of the hydric 165 166 environment in each population, which fitted well with our direct observation in the field (Dupoué, pers. obs.). 167

168 *Genetic data*

Genomic DNA was extracted from swabs using the DNeasy 96 Blood and Tissue Purification 169 170 Kit (QiagenTM, Hilden, Germany) according to the manufacturer's instructions. We amplified sixteen microsatellite markers (Table S2) in 5µl reaction volumes with 1µl of PCR 171 172 master Kit (MPBiomedicals) and 5-10ng of template DNA. PCR products were run on an ABI 3730 DNA Analyser (Applied Biosystems) with Genescan-600Liz size standard. Genotyping 173 was performed with Genemapper 5.0 (Applied Biosystems). We performed an initial 174 175 examination on the dataset to retain the loci with limited allele dropout (< 18% of missing 176 data). Ambiguous genotypes were amplified and sized a second time. Out of 16 initial loci, 5 loci were rejected from further analyses due to an excess of missing data (Table S2). Null 177 178 alleles and linkage disequilibrium among remaining loci was tested using GENEPOP 4.7.0 (Rousset, 2008) following 10,000 iterations. The 11 loci did not present significant evidence 179 for null alleles (Table S2), nor linkage disequilibrium (Table S3) and were used in the 180 181 following analyses. We used COLONY software (Jones & Wang, 2010) to identify and remove relatives in each population (Table S4) given that they may alter subsequent analyses 182 (Rodríguez-Ramilo & Wang, 2012). The final dataset included n = 599 individuals. 183 Statistical analyses

Genetic metrics 185

184

186 We used R software (R Development Core Team 2015) and the DiveRsity R-package (Keenan

et al., 2013) to estimate genetic diversity in each population including expected 187

heterozygosity (He), observed heterozygosity (Ho), deviation test to Hardy-Weinberg 188

equilibrium (HWE), and allelic richness (Ar). We used the same package to estimate 189

heterozygote deficit within a population (F_{IS}) and genetic differentiation between populations 190

191 (F_{ST}) after 1,000 bootstraps. In all these analyses, we excluded one population (Lagunas,

Table S1) given that the sample size (n = 6 lizards) was too small to obtain reliable estimates 192

of population genetic diversity. We used the poppr R-package (Kamvar et al., 2015) to 193

analyse the molecular variance (AMOVA) and check how variation in genetic diversity 194 195 differed i) among ecological units, ii) among or within populations, and iii) within individuals. We used the program BOTTLENECK (Piry et al., 1999) to check if any 196 197 populations experienced a recent bottleneck. Shortly after a bottleneck event, heterozygosity increases more rapidly than allelic diversity (Piry et al., 1999). The program tests the 198 heterozygosity excess and compares Ho and He (Wilcoxon test) after 1,000 iterations. We 199 200 considered a two phase model including a 95% of stepwise mutation model and a variance of 12 as recommended (Piry et al., 1999). 201

202 <u>Genetic structure</u>

We used the Bayesian clustering analysis of the program STRUCTURE 2.3.3 (Pritchard et al., 203 2000) to determine whether populations could be regrouped without a priori information. We 204 205 determined how many clusters (K) best fit with our data, based on ΔK method (Earl & VonHoldt, 2012). To do so, we ran 10 independent simulations for each K ranging from 1 to 206 207 42, with 500,000 iterations and a burn-in period of 100,000 steps. We adjusted the burn-in 208 period to 200,000 steps in another simulation with K ranging from 1 to 10, to check that the 209 initial burn-in period was sufficiently long to ensure model convergence. We compared two outputs (alpha and likelihood) from the program, illustrating relatively few admixtures 210 211 between population (alpha < 1) and good model convergence (Fig. S2). We estimated 212 structuration of each population as the highest probability (maximal Q-value) for an individual to be affiliated to a cluster (Fig. 1). 213

We complemented this analysis by using another method for the examination of
population structure. We considered a method based on Discriminant Analysis of Principal
Component (DAPC) proposed by Jombart et al., (2010) and implemented in the *adegenet* R
package (Jombart, 2008). This multivariate method generates models for a range of *K* clusters
and calculate Bayesian Information Criterion (BIC) after 10,000 iterations (Jombart et al.,

219 2010). Optimal *K* is chosen following a stepping stones approach, for the minimum *K* when220 BIC decreases by a negligible amount (Fig. S3).

221 <u>Genetic connectivity</u>

We examined the degree of isolation-by-distance (IBD) using Mantel tests implemented in the adegenet R package. We compared the relationships between pairwise genetic distances and pairwise Euclidian geographic distances either globally (i.e., analysis on the entire dataset) or locally (i.e., analyses within each ecological unit). We considered chord genetic distances (D_C) between populations defined by (Cavalli-Sforza & Edwards, 1967), since these are more likely to retrieve correct relations among populations (Takezaki & Nei, 1996). P-values were

generated by comparing observed and predicted distributions after 1,000 iterations.

229 Effect of environmental conditions on demography and genetic diversity

We used AICc based model selection and averaging from the MuMIn R-package (Barton, 230 231 2019) to examine the additive impacts of climate conditions and habitat characteristics on 232 lizard abundance (calculated from field data) and genetic diversity [calculated with DiveRsity R package (Keenan et al., 2013)]. We ran four independent sets of 15 linear mixed model [R 233 package nlme (Pinheiro et al., 2016)] comparisons, using either demographic (lizard 234 235 abundance) or genetic markers (Ar, F_{IS} and F_{ST}) as response variables, and environmental covariates alone or in addition (see models detailed in Table 1). Level of correlation between 236 237 environmental variables was below 0.42, thus limiting the risk of multicollinearity issue (Dormann et al., 2013). In all models, ecological unit was set as a random term to account for 238 spatial interdependence of populations. For each demographic or genetic parameter, we 239 inferred the best models from the AICc score [Δ AICc < 2 (Burnham & Anderson, 2002)], and 240 calculated the conditional model average to test for effect size and significance of fixed co-241

variates. We verified that residuals of all selected models (Table 1) respected normality
conditions (Shapiro test: all p > 0.104).

244 <u>Pyrenean colonisation scenarios</u>

We used Approximate Bayesian Computation (ABC) to test different Pyrenean colonisation 245 scenarios using DIYABC 2.1.0 (Cornuet et al., 2010). First, we determined if variation in 246 population genetics within and between ecological units coincided to an ancient or a recent 247 248 Pyrenean colonisation. We followed the same methodology as described in (Ursenbacher et al., 2015) and generated $3 \cdot 10^6$ simulations to compare the posterior probabilities (logistic 249 regression) of three scenarios (Fig. 2) including: a simultaneous split among the four 250 ecological units (scenario 1), an altitudinal progressive colonisation (scenario 2) and a 251 simultaneous split in the Pyrenees regions differing from the rear edge (scenario 3). We 252 253 restricted the number of tested scenarios by ordering ecological units based on their altitudinal class (Fig. 2). However, we did not test for scenarios with higher proximity between the rear 254 255 and the leading edge compared to others units since it has no biological meaning. Once the most likely scenario was identified, we further ran $4 \cdot 10^6$ iterations to estimate the parameters 256 257 (effective population size: N, and divergence time: t). We defined N1 < N2 < N3 > N4 and t3 > t2 > t1 as conditional priors (Fig. 2) and we considered the mean number of alleles, the 258 259 mean gene diversity, the mean size variance, and, between two samples, the F_{ST}, the mean index of classification, the shared allele distance, and the $(d\mu)^2$ distance as summary statistics. 260 We checked the performance of each ABC analysis (scenario comparison and parameters 261 estimation) by simulating 500 pseudo-observed datasets, comparing their posterior 262 distribution, and compiling relative error (Cornuet et al., 2010). We used a generation time of 263 3 years based on the equation $T = \alpha + [s/1(1-s)]$ (Lande et al., 2003) where α is the age at 264 maturity and s is the annual survival rate. Survival and age at maturity are likely to vary along 265 altitude (Heulin et al., 1997), so we considered adult survival rate of 0.51 (low and 266

intermediate altitudes) or 0.32 (high altitudes) and a recruitment in reproduction at one yearold (low and intermediate altitudes) or 2 years old (high altitudes).

269 **Results**

270 <u>Genetic diversity</u>

Analyses of molecular variance showed that genetic diversity varied mostly within individuals 271 (86.8%), but a substantial and significant part of variation was also explained within 272 273 populations (4.1%) and between populations (7.4%) followed by a minor variation between ecological units (1.7%, see Table S5). Within population diversity and population 274 differentiation varied among ecological units (Ar: $F_{3,37} = 3.7$, p = 0.020; F_{IS} : $F_{3,37} = 4.6$, p =275 0.008; F_{ST} : F_{3.37} = 4.2, p = 0.012). Ar was the highest in the admixture zone and F_{IS} were 276 highest in the rear edge and decreased along altitudinal clines (Fig. 3a & 3b). F_{ST} was higher 277 278 in both the rear and leading edge but the lowest in the admixture zone (Fig. 3c). We did not 279 find any evidence for a recent bottleneck (p > 0.216), except in one population (BTM, p =0.002). 280

281 <u>Genetic structure</u>

Both the Bayesian spatial modelling of genetic population structure and the ordination method gathered populations into K = 6 clusters (Table S6 & Fig. S2). Clustering was relatively heterogeneous between and within ecological units, and rather dependent on population locality (Fig. 1). Yet, structuration (i.e., the probability for an individual to be affiliated to a cluster) differed significantly between ecological units (F_{3,38} = 3.5, p = 0.024) since there was a lower structuration in the admixture zone compared to the 3 other ecological units (pairwise comparisons, all p < 0.032).

289 <u>Genetic isolation</u>

Isolation by distance (IBD) was highly significant globally (p = 0.001, Fig. 4a). Locally

291 however, IBD differed among ecological units and according to isolation level. IBD was non-

- significant at both the rear edge (p = 0.276, Fig. 4b) and the admixture zone (p = 0.320, Fig.
- 4c), where all pairwise geographic distances were below 60 km. Instead, significant IBD was
- found in both the continuous range (p = 0.006, Fig. 4d) and the leading edge (p = 0.003, Fig.
- 4e) where many pairwise geographic distances were above 60 km.

296 Effect of past and present environmental conditions on demography and genetic diversity

Spatial variation in lizard abundance was correlated solely to air temperature (Table 1, Fig. 5a), with the most scattered populations associated to warm environments. Ar was the lowest under warm and dry climates, and in open habitats (Table 1, Fig. 5b). Variation in both F_{IS} and F_{ST} were better explained by additive constraints in temperature and forest cover (Table 1, Fig. 5c & 5d). That is, inbreeding and differentiation is higher in warm and open habitats (Table 1).

303 Pyrenean colonisation scenarios

The most likely scenario was the colonization scenario 2 with a posterior probability of $0.86 \pm$ 304 0.04 (Fig. 2). We compared logistic distribution in 500 simulated datasets to estimate a global 305 306 posterior predictive error of 0.17, a type I error (probability of rejecting scenario 2 when it is the correct scenario) of 0.33 and a type II error (probability of choosing scenario 2 when it is 307 308 an incorrect scenario) of 0.22. Effective population size considerably varied between ecological units ranging from 1,500 in the leading edge to 9,000 reproductive individuals in 309 the continuous range (Table 2). The split between the rear edge and the other populations 310 311 occurred 750 generations ago, thereby placing the start of the Pyrenean ascension to around 2,000 years ago (Table 2). The divergence in the other ecological units occurred very recently 312

in the last millennium, with evidence of high elevation colonization between 100 and 700years before present (Table 2).

315

316 **Discussion**

Genetic diversity was relatively high amongst lizards or across populations in the 317 geographic area and reasonably follows the theoretical predictions of the rear-leading edges 318 319 model of population genetic diversity and structure (Hampe et al., 2013; Hampe & Petit, 2005). That is, populations at the rear edge experience strong levels of inbreeding (loss of 320 321 heterozygosity). Associated with this, pairwise genetic distances were not correlated to geographic distances neither within the rear edge nor in the admixture zone, probably due to 322 recently interrupted gene flow. From the continuous range to the leading edge, populations are 323 324 mostly isolated by distance, which suggests continuous distance-limited gene flow over time. 325 However, lower allelic richness and high differentiation in the leading edge populations imply that they likely originated via small groups of immigrants through founder events (Hampe et 326 327 al., 2013; Nadeau & Urban, 2019; Waters et al., 2013). Lower inbreeding levels in these colonized areas might for instance reflect a purge of inbred individuals during recruitment 328 (Hampe et al., 2013), since this species can optimise mate choice for that purpose (Richard et 329 al., 2009). 330

Our results provide new insights on genetic diversity and structuring of the subclade B2 of *Zootoca vivipara*. Concomitantly with the geographic distribution of six genetic units highlighted here, previous studies have shown that the strong genetic structuration of the clade B is strongly shaped by mountain barriers and phylogeography (Horreo, Breedveld, et al., 2019; Horreo, Peláez, et al., 2019; Milá et al., 2013). Genetic introgression between southern Pyrenees (in Spain) and northern Pyrenees (in France) subclades is also common

among high altitude populations following secondary contacts associated with range shifts in 337 338 warmer climates (Horreo, Breedveld, et al., 2019; Milá et al., 2013). This pattern of genetic introgression in the high elevation mountain range may explain why a population such as 339 340 ARA sampled at high altitude and near a contact zone (Table S1) may have its own genetic structure. In our study, we further found that the highest allelic richness and lowest 341 342 differentiation or structuration was found in the admixture zone, as this area may represent a 343 mixing zone between genetic lineages of the rear edge populations and those from the continuous range (Hampe & Petit, 2005). Yet, mixing between populations arises despite 344 obvious isolation and interrupted gene flow. Therefore, we hypothesize this specific pattern in 345 346 the admixture zone to reflect ancient (structuration) versus recent (isolation) events caused by climate conditions and habitat fragmentation (Päckert et al., 2019). Surprisingly however, we 347 found little evidence for bottlenecks (only one population likely due to a local isolation by a 348 349 road), contrary to Horreo, Peláez, et al., (2019) who documented recent bottlenecks and significant heterozygote deficiencies in most clade B populations. This difference can be 350 351 caused by methodological bias [n = 11 loci in the present study, n = 28 loci in (Horreo,352 Peláez, et al., 2019)] and a resulting lack of statistical power to detect recent bottlenecks. Further investigations including more microsatellites will help to better track recent genetic 353 354 changes in the studied area.

A complementary study of the clade B populations further suggested that recent global warming may explain low migration rates and recent bottlenecks (Horreo, Peláez, et al., 2019). In support of a scenario of range contraction and expansion together with genetic structuring shaped by global changes, we showed here that climate conditions and forest cover explained additively variation in lizard demography and population genetics. Specifically, warmer temperatures in lowland populations were associated with lower lizard abundance and higher levels of inbreeding and genetic differentiation. Therefore, in addition

to relatively low effective population size, populations at the hot margin of the distribution 362 363 may be at greater risk of extinction (Cornetti et al., 2015; Templeton et al., 2001). Indeed, comparative studies in contemporary populations of the viviparous form of this species have 364 shown that heat and drought represent important causal determinants of physiological stress, 365 reduction of behavioural activity and eventually population collapse (Bestion et al., 2015; 366 Dupoué et al., 2018, 2020; Dupoué, Rutschmann, Le Galliard, Clobert, et al., 2017; Massot et 367 368 al., 2008). Furthermore, forest cover systematically exhibited an additive influence on withinpopulation diversity, inbreeding, and genetic differentiation. That is, contemporary 369 populations located in the most open habitats exhibit higher inbreeding under warm climates 370 371 (low altitude) and experience poorer allelic richness and higher differentiation under cold climates (high altitude). Although this species typically occupies open habitats (meadows, 372 peat-bogs, heathlands) to perform daily activities, mixed habitats with proximity to dense 373 374 forests might represent more intact habitat landscapes. In addition, lizards in populations next to or mixed with forest patches are better capable of adjusting their breeding phenology 375 376 (Rutschmann et al., 2016) and their thermoregulation behaviour (Rozen-Rechels et al., in press). Mixed forest habitats might therefore allow lizards to buffer negative consequences of 377 extreme weather events. Our population genetics study thus suggests that this cold-adapted 378 379 ectotherm may maintain small populations, especially at low altitudes, depending on proximity to forest cover, possibly serving as 'thermal refuges' during resting periods. Hence, 380 the preservation of these habitats might represent a key conservation action to protect this 381 lizard and the associated cortege of species (Jofré et al., 2016). There is now a critical need 382 for developing genetically informed ecological niche models to better predict future species 383 distributions under cumulative constraints of climate change and landscape structuration 384 (Carvalho et al., 2019; Ikeda et al., 2017; Razgour et al., 2019). 385

Our results also revealed that the altitudinal colonisation of the Pyrenees started over 386 387 the past two millennia (< 2 kya), much more recently than we expected (~10 kya following) the LGM). Splits were particularly recent between the foothill and upward populations (~400 388 years), and between highland populations (~100 years), thus confirming a rapid and recent 389 range expansion. Errors in scenario selection and parameters estimations were relatively low 390 391 and in the range of acceptable error to be confident in observed results (Cornuet et al., 2010). 392 The most likely and parsimonious scenario for such recent ascension relates to the combined 393 effects of habitat restructuration and recent climate change. Following the LGM, the present continuous range and leading edges were likely impassable for such a heliothermic lizard 394 395 given that above 1,000 m, the Pyrenees were at the time entirely covered by dense pine forest (Davasse et al., 1996). As unravelled by palynology, this area was mostly deforested during 396 the Middle Ages to develop pastoralism (Galop et al., 2003; Zanon et al., 2018), which 397 398 probably opened new habitats and a new climbing path for this species. Additionally, climate conditions in the Pyrenees likely became suitable only after the Little Ice Age when the 399 400 mountain glaciers retreated starting since approximately 1850. Our findings are consistent 401 with similar insights related to the recent genetic differentiation (~200 years) in the same 402 geographic area of the Pyrenean Desman (Galemys pyrenaicus), an endemic semiaquatic 403 mammal affiliated to rivers and streams (Gillet et al., 2017).

Retracing population history of wild species is important if we are going to correctly
interpret current distributions and foresee future impacts of global warming on demographic
trends. In short, this study provides a rare example supporting general theoretical predictions
stemming from the rear-leading edge conceptual framework (Hampe et al., 2013; Hampe &
Petit, 2005; Nadeau & Urban, 2019; Razgour et al., 2013; Vilà-Cabrera et al., 2019; Waters et
al., 2013). Rear edge populations showed the alarming lowest genetic diversity and highest
inbreeding, interrupted gene flows and lower population size, which put them at greater risk

of extinction. Ground-dwelling ectotherms usually display relatively low dispersal rates
(Stevens et al., 2014), yet our study challenged this generality and suggested fast colonisation
capabilities in the common lizard likely facilitated by past habitat connectivity. Together, our
results therefore illustrate the importance of integrating genetic diversity, differentiation and
colonisation capabilities to accurately characterise and anticipate the potential footprints of
global change on wild species and ecosystems.

688 Acknowledgements

689 We are particularly grateful to the associations 'Nature en Occitanie' and 'Cistude Nature'

690 who provided the database that allowed us to localize the great majority of lizard populations,

- and we thank the 'Parc National des Pyrenees' for authorizing us to sample lizards. We also
- thank Dr Sylvain Ursenbacher for advice on genetic analyses.

693 Funding

- This study received the financial and technical support from the Centre National de la
- 695 Recherche Scientifique (CNRS), and was funded by the Interreg Poctefa under the project
- 696 'Ectopyr' (no. EFA031/15 to FA), by the Agence Nationale de la Recherche under the
- 697 'Aquatherm' project (ANR-17-CE02-0013 to JFLG), by the European Union (Feder), the
- regional council of Nouvelle Aquitaine, and the departmental council of Gironde & Pyrénées-
- 699 Atlantiques under the 'Climate Sentinels' project (coordinators: Cistude Nature, Fanny
- Mallard), and under the 'Aquastress' project (2018-1R20214 to OL).
- At the time of writing, AD was financially supported by the Australian Research Council (no.
 DP180100058 to A/Prof Anne Peters).

703 Ethics

- The collection of samples was approved by the "Conseil Scientifique Régional du Patrimoine
- Naturel (CSRPN)" of the region Occitanie. Procedures complied with current French
- regulations permit (#2017-s-02) relating to an authorization of capture, marking, transport,
- 707 detention, use and release of protected lizard species.

708 Author contributions

- AD and AT conceived the study together with JC and FA. AD, MR, MS, JTQ, CV, CR,
- 710 MauB, MatB, OL and PB captured lizards. MR and MS performed molecular assays. AD, AT

711	and MG performed the	e data analyses. I	RB and MG participated i	n environmental data
-----	----------------------	--------------------	--------------------------	----------------------

- extraction. MauB, MatB and GP initially identified lizard populations sampled in this study.
- AT, RB, OC, OG, HLC, JS, JFLG, JC, and FA were involved in funding and planning this
- vork. AD led the sampling design and draft the manuscript. All authors commented the
- article and gave final approval for publication.

716 Biosketch

- 717 Andréaz Dupoué is interested in depicting which are the proximate mechanisms driving
- 718 population extirpation. His main researches at the interface between molecular ecology and
- recological physiology emphasize the importance of water based trade-offs in the evolution of
- vild squamate reptiles.
- 721 The research team lead multi-specific studies on Pyrenean and European ectotherms.
- 722

723 Data accessibility

- The data supporting this article are available at the Zenodo Repository at
- 725 http://doi.org/10.5281/zenodo.4266021

726 Table 1. Model selection comparing the impacts of climate (temperature and precipitations) and habitat quality (forest cover and

vetland potential) on lizard demography (abundance) and genetic profile [allelic richness (Ar), inbreeding (*F*_{IS}) and differentiation

728 (*F*st)]. For each population parameter, the table reports the \triangle AICc based linear mixed model comparison and full averages of fixed covariates.

Ecological unit was set as a random term in all models to account for spatial interdependence.

730

df: degree of freedom, logLik: log likelihood, $\Delta AICc$: difference in corrected Akaike Information Criterion relative to model with lowest AICs.

Highlighted models (grey area) are based on $\Delta AICc < 2$. Highlighted variables (bolded characters) are based on $\alpha < 0.05$.

 Table 2. Posterior estimations of demographic parameters (means and 95% CI)
 734 following 4.10⁶ simulations and splits designed under scenario 2 (see Fig. 2). Table 735 reports the effective population size (Ne) of each ecological unit, and the generation time 736 before sampling associated with each out three divergence times (split of the rear edge: t1, 737 split of the admixture zone: t2, and separation of the leading edge from continuous range: t3; 738 see Fig. 2). For each parameter, we estimated estimation accuracy by generating 500 datasets 739 and compile the Relative Median Absolute Error (RMAE) based on their posterior 740 741 distributions. The corresponding number of years were assumed considering a generation time of three years. See text for details. 742

743

Ecological units	Ne	95% CI	RMAE			
Rear edge (< 100 m)	6,100	2,170 – 10,030	0.169			
Admixture zone (100-500 m)	6,390	2,580 – 10,200	0.146			
Continuous range (500-1300 m)	8,730	2,710 – 14,750	0.104			
Leading Edge (> 1300 m)	1,600	1,014 – 2,186	0.171			
	Generations	95%CI	RMAE	Generation time	Years	95%CI
t1	37	21 - 53	0.262	2.5	92.5	52.5 - 132.5
t2	191	108 - 274	0.211	2.0	382	216 - 548
t3	748	536 - 960	0.120	2.0	1,496	1,072 - 1,920

745 **Figure captions**

746 Fig. 1. Genetic structuration of 42 natural populations of the common lizard (Z. v.

747 *louislantzi*) gathered into 4 ecological units associated with the recent shift in

distribution of the Western clade. Individuals (n = 599) were clustered without *a priori* into K = 6 clusters (one colour per *K*) following a Bayesian approach (top panel). We used the maximal proportion of individuals affiliated to a cluster within a population (as illustrated by the 42 pie charts) to represent an index of population structuration. Although structuration depended on ecological units (mean ± SE on the right panel), the different clusters depended on geographic localisation rather than ecological units (bottom panels).

754

Fig. 2. Three demographic scenarios of Pyrenean ascension in the common lizards. For 755 756 each ecological unit, the total population size (N) was kept constant. Posterior estimates of 10^6 simulations for each scenario were compared using logistic regression and scenario 2 was 757 retained with the highest posterior probability (mean \pm 95% CI: 0.74 \pm 0.06), compared to 758 759 scenario 1 (0.10 \pm 0.04) and scenario 3 (0.16 \pm 0.17). The selected scenario associates three divergence times between ecological units across Pyrenean ascension (split of the rear edge: 760 t1, split of the admixture zone: t2, and separation of the leading edge from continuous range: 761 t3). 762

763

Fig. 3. Comparison of population genetics (means ± SE) among ecological units and

associated predictions (grey polygons). (a) Within-populations genetic diversity decreases
across altitude much like (b) inbreeding, while (c) genetic differentiation follow a non-linear
trend following our predictions.

769

770	Fig. 4. Population connectivity tested by isolation by distance (IBD) both globally and
771	locally. Significant relationships between genetic distance and geographic distance are
772	symbolized with line types (solid: significant, dashed: non-significant) together with a 2-
773	dimensional kernel density estimation to illustrate population continuity. (a) Globally, genetic
774	distances are associated with geographic distance and continuous, (b,c) IBD was non-
775	significant in isolated populations, and (d,e) IBD was significant but discontinuous in
776	connected populations.
777	
778	Fig. 5. Variation of demographic and genetic markers with climate conditions and
779	habitat characteristics. The line and surfaces are drawn from predictions of the best linear
780	mixed models selected by the best conditional average (Table 1). The color gradient
781	highlights the values from low (blue) to high range (orange). a) Lizard abundance was
782	negatively correlated solely to air temperature, while b) within-population diversity, c)
783	inbreeding or d) population differentiation were influenced by additive effects of air
784	temperature and forest cover.
